Optimizing Remote Accesses for Offloaded Kernels:
Application to High-Level Synthesis for FPGA

Abstract—Some data- and compute-intensive applications can be accelerated by offloading portions of codes to platforms such as GPGPUs or FPGAs. However, to get high performance for these kernels, it is mandatory to restructure the application, to generate adequate communication mechanisms for the transfer of remote data, and to make good usage of the memory hand-width. In the context of the high-level synthesis (HLS), from a C program, of hardware accelerators on FPGA, we show how to automatically generate optimized remote accesses for an accelerator communicating to an external DDR memory. Loop tiling is used to enable block communications, suitable for DDR memories. Pipelined communication processes are generated to overlap communications and computations, thereby hiding some latencies, in a way similar to double buffering. Finally, not only intra-tile but also inter-tile data reuse is exploited to avoid remote accesses when data are already available in the local memory.

Our first contribution is to show how to generate the sets of data to be read from (resp. written to) the external memory just before (resp. after) each tile so as to reduce communications and reuse data as much as possible in the accelerator. The main difficulty arises when some data may be (re)defined in the accelerator and should be kept locally. Our second contribution is an optimized code generation scheme, entirely at source-level, i.e., in C, that allows us to compile all the necessary glue (the communication processes) with the same HLS tool as for the computation kernel. Both contributions use advanced polyhedral techniques for program analysis and transformation. Experiments with Altera HLS tools demonstrate how to use our techniques to efficiently map C kernels to FPGA.

I. INTRODUCTION

HLS tools [1], e.g., Catapult-C, Impulse-C, Pico-Express, C2H, Gaut, Spark, Ugh, provide a convenient level of abstraction (in C-like languages) to implement complex designs. Most of these tools integrate state-of-the-art back-end compilation techniques and are thus able to derive an optimized internal structure, thanks to efficient techniques for scheduling, resource sharing, and finite-state machines generation. However, integrating the automatically-generated hardware accelerators within the complete design, with optimized communications, synchronizations, and local buffers, remains a hard task, reserved to expert designers. In addition to the VHDL glue that must sometimes be added, the input program must often be rewritten, in a proper way that is not obvious to guess. For HLS tools to be viable, these issues need to be addressed: a) the interface should be part of the specification and/or automatically generated by the HLS tool; b) HLS-specific optimizing program restructuring should be available, either in the tool or accessible to the designer, so that high performances (mainly throughput) can be achieved. High-level transformations and optimizations are common in high-performance compilers, not yet in high-level synthesis. But their interest and their specificities for HLS have been demonstrated through handmade designs or restructuring methodologies [2], [3], [4], [5].

The goal of this paper is to show how the handmade restructuring proposed in [5] in the context of C2H, the Altera HLS tool, can be fully automated, thanks to advanced polyhedral techniques for code analysis and code generation, entirely at source level (i.e., in C). We focus on the optimization of hardware accelerators that work on a large data set that cannot be completely stored in local memory, but need to be transferred from a DDR memory at the highest possible rate, and possibly temporarily stored locally. For such a memory, the throughput of memory transfers is not uniform: successive accesses to the same DDR row are pipelined an order of magnitude faster than when accessing different rows. Consequently, accessing data by blocks is a direct way of improving performances: if not, the hardware accelerator, even if it is highly-optimized, keeps stalling and runs at the frequency of the DDR accesses. A similar situation occurs when accessing a bus for which burst communications are more efficient or when optimizing remote accesses for GPGPUs. More generally, this offloading problem occurs when transfers between an external large memory and an accelerator with a limited memory should be reduced (thanks to data reuse in the accelerator), pipelined, and preferably performed by blocks. This is why our optimization techniques, although developed for HLS and specialized to Altera C2H, may be interesting in other contexts.

Our technique relies on loop tiling to increase the granularity of computations and communications. Each strip of tiles is optimized as follows. Transfers from and to the DDR are pipelined, in a blocking and double-buffering fashion, thanks to the introduction of software-pipelined communicating processes. Data reuse within a strip, in particular inter-tile reuse, is exploited by accessing data from the accelerator and not from the DDR when already present. Local memories are automatically generated to store the communicated data and exploit data reuse. Our main contributions are the following:

Program analysis We show how to compute the sets Load(T) and Store(T) of data to be loaded/stored before/after the execution of a tile T, thanks to parametric linear programming, so that the lifetime of each individual data in the local memory is minimized, which tends to reduce its size. Unlike previous approaches, ours can pipeline communications and exploit reuse among tiles even for data redefined in the tile strip. It can also be extended to the case where data accesses are approximated, i.e., when reads/writes are not known for sure.
Code generation Driven by a “scheduling function” that expresses the tiling of loops and the pipelining of tiles, our technique generates automatically the size of local buffers, the access functions, the scanning of data sets to access the DDR row-wise, and the generation of communicating processes, thanks to the integration of several polyhedral techniques.

HLS integration A unique feature of our scheme is that the original computation kernel and all generated communicating processes are expressed in C and compiled into hardware with the same HLS tool (C2H), used as a back-end compiler.

In Section II, we recall loop tiling and illustrate our technique through a synthetic example. Section III explains how to optimize remote accesses for an offloaded kernel, when the sets of data read and written in a tile are known exactly. In Section IV, we apply our technique to the special case of HLS with Altera C2H. We present the different steps of the code generation and some experimental results comparing the performances of the hardware accelerators of [5], optimized by hand, and those optimized automatically thanks to our method.

II. LOOP TILING AND TRANSFER SETS

Our method can be applied to offload a kernel on which loop tiling [7] and polyhedral transformations can be applied, i.e., a set of for nested loops, manipulating arrays and scalar variables, whose iterations can be represented by an iteration domain using polyhedra, i.e., when loop bounds, if conditions, and array access functions are affine expressions of surrounding loops counters and structure parameters. Many compute-intensive kernels (e.g., from linear algebra, image processing) fit into this model.

Loop tiling is a standard loop transformation, known to be effective for automatic parallelization and data locality improvement. With loop tiling, the iteration domain is partitioned into rectangular blocks (tiles) of iterations to be executed atomically. Loop tiling can be viewed as a composition of strip-mining and loop interchange. Strip-mining introduces two kinds of loops: the tile loops, which iterate over the tiles, and the intra-tile loops, which iterate within a tile. This step is always legal. Then, loop interchange pushes the intra-tile loops to innermost positions. In some cases, a first loop transformation, e.g., loop skewing, is needed to make the loops tilable (i.e., fully permutable). “Rectangular” has to be understood w.r.t. this preliminary change of basis.

We call tile strip the set of tiles described by the innermost tile loop, for a given iteration of the outer tile loops. This notion is widely used in our approach, as our optimizations are performed within such a one-dimensional tile strip, parameterized by the counters of the outer tile loops. A loop tiling for a statement $S$, within $n$ nested loops with iteration domain $D_S$, can be defined thanks to an $n$-dimensional affine function $i \mapsto \theta(S, i)$ (the permutable dimensions), where $i$ is the iteration vector scanning $D_S$, and a (single, to make things simpler) tile size $b$. Then, a tile, defined by $n$ loop counters $I_1, \ldots, I_n$, contains $i \in D_S$ if $b_1 i_1 \leq \theta(S, i) < b(I_1 + 1)$, for $k \in [1..n]$. Adding these constraints, for a fixed value $b$,

---

1This restriction is enough for the kernels of Section IV and, more generally, when reads are approximated. When writes are approximated, the technique can be extended [6], but this goes out of the scope of this paper.

2For the automatic selection of tile directions and size, see for ex. [7], [8].
The execution of each tile $T$ is then decomposed, thanks to communication coalescing (see Section III), into three pipelined processes, for loading data, storing data, and performing the computations, as required for $T$. The function $\theta$ is then also used to express the relative schedules of these processes and to help us synthesize the adequate local buffers in a double-buffering fashion. Actually, “double-buffering” is a language simplification: we will not use two buffers, but one single (larger) buffer. However, two successive blocks of computation in a tile strip are indeed pipelined with two blocks of communications, which results in an overlapping between communications and computations (see Section IV).

To define the transfer sets $\text{Load}(T)$ and $\text{Store}(T)$ expressing the data to be loaded/stored before/after the execution of a tile indexed by $T$, we make the following assumptions:

- Elements in $\text{Load}(T)$ are loaded from external memory before the tile $T$ starts, but in any order for a given $T$.
- Elements in $\text{Store}(T)$ are stored to external memory after the tile $T$ ends, but in any order for a given $T$.
- Tiles are executed in sequence, following the sequential order specified by $\theta_{\text{tile}}$, in particular with increasing $T$.
- Similarly, transfers in $\text{Load}(T)$ (resp. $\text{Store}(T)$) are initiated before those in $\text{Load}(T')$ (resp. $\text{Store}(T')$) if $T < T'$.

In addition, we will make sure that a data is never loaded from the external memory if it has already been loaded earlier. Instead, it will be kept in local memory until its last use.

**Back to the example:** Consider Fig. 1 with the left tiling corresponding to $(i, j) \to (I, J, i, i+j)$ where $ii = N - j$ and $jj = i$. Our technique determines that the elements of $c$ to be loaded are those depicted in grey boxes, indicated as “First read (c)”.

For that, given $3$ parameters, the loop bound $N$, the outer tile index $I$, and the memory index $m$ of array $c$, we derive (here for $b = 10$) an expression of the initial loop indices $(i, j)$ that perform the first reads of $c$ in the tile strip:

- $(i, j) = (0, m)$ if $0 \leq -10I + N - m \leq 9$ (this case corresponds to a vertical portion of $c$);
- $(i, j) = (10I - N + m, N - 10I)$ if $1 \leq 10I - N + m \leq N$ (this corresponds to an horizontal portion).

Then, we derive $\text{Load}(T)$ (here $T = J$ with previous notations) as the set of data $m$ read in $T$ if this is the first access in the tile strip indexed by $I$:

$$\{m \mid \max(0, N - 10I - 9) \leq m \leq N - 10I, T = 0\} \cup \{m \mid \max(1, 10T) \leq m + 10I - N \leq \min(N, 10T + 9)\}$$

How to get these load/store sets (basically, first read/last writes) in general, how the corresponding transfers are orchestrated, and how the necessary local memories are dimensioned and addressed, is detailed in the rest of this paper.

### III. Communication Coalescing

We now show how to select the array regions to be loaded from and stored to the external DDR memory. This step impacts the amount of communications, the lifetime of array elements in the local memory, and the size of this memory.

To perform data transfers, the most naive solution is to access the DDR for each remote data access in the code. This solution does not require any local memory but is very inefficient: the latency to the DDR has to be paid for each access, which takes roughly $400$ ns on our platform. Accesses must thus be pipelined (a feature available in Altera C2H) so that the accelerator throughput depends not on the DDR latency, but on its throughput. The accelerator can then receive $32$ bits every $80$ ns, if successively-accessed data are not in the same DDR row. However, if data accesses are reorganized by blocks on the same row, thanks to loop tiling, the accelerator can work at full rate, i.e., it can receive $32$ bits every $10$ ns. But to sustain this rate and not pay any DDR latency, communications must be fully pipelined. This can be done thanks to communication coalescing, which amounts to hoisting transfers out of a tile and to regrouping the same accesses to eliminate redundancy.

Communication coalescing is a common optimization in compilers, for optimizing communications and scratch-pad memories [9], [10], [11], [12], [8], [13], [14], [15]. The form of communication coalescing we develop here is different as it exploits not only intra-tile reuse but also inter-tile reuse, even if data dependences exist between tiles, at the granularity of individual array elements. Usually, the approach is to load, just before executing a tile, all the data read in the tile, then to store to the DDR all data written in the tile. This solution does not exploit inter-tile data reuse and, unless no data-flow dependence exists between successive tiles, forbids to overlap computations and communications. This is the approach implemented in the RStream compiler, as described in [13]. The other extreme solution is to first load all data needed in a tile strip, then to execute all tiles in the strip, and finally to store to the DDR all data produced by the tile strip, in other words, to hoist some communications outside the innermost tile loop. This exploits data reuse but requires a large local memory to store all needed data. Also, computations cannot start before all data have arrived. Another important difference is that our technique performs loads from the external memory even when this memory is not fully up-to-date.

Our strategy consists of sending load and store requests to the DDR only at the time they are needed. Furthermore, we load from (resp. store to) the DDR any data read (resp. written) in the current tile strip only once. Between the first and the last accesses, the data is kept and used (read and written) in the local memory, exploiting data reuse. As a bonus, this method handles naturally the case where dependences exist between tiles of a tile strip. Indeed, as data concerned by inter-tile dependences are kept in local memory, the sequential execution of tiles guarantees the program correctness. Another consequence is that, unlike for previous approaches where the resulting lifetimes of array elements are all the same (either from the first tile to the last tile, or just within a tile), memory allocation based on bounding box as in [13], [10], [8] is not enough: to exploit the different lifetimes of individual array elements, we need to use a more general allocation scheme, based on modular mappings, as explained in Section IV-B.

Our technique relies on the following definitions and theorems. For a tile $T$, let $\text{In}(T)$ be the data read in $T$, but not defined earlier in the tile, i.e., used in $T$ and live-in for $T$, and let $\text{Out}(T)$ be the data written in $T$. We assume $\text{In}(T)$ and $\text{Out}(T)$ to be exact. The following theorem gives a solution where loads are performed as late as possible and stores as soon as possible. This has the effect of minimizing the lifetime.
Theorem 1: The functions Load and Store defined by
- \( \text{Load}(T) = \{ \vec{m} \mid \text{FirstOpReadBeforeWrite}(\vec{m}) \in T \} \)
- \( \text{Store}(T) = \{ \vec{m} \mid \text{LastOpWrite}(\vec{m}) \in T \} \)

avoid useless transfers and reduce lifetimes in local memory.

Theorem 1 specifies optimized transfers based on set operations. Instead of relying on such operations, which could be done with the libraries Omega or ISL\(^3\), our implementation uses an alternative approach based on PIP, a tool for parametric linear programming [16]. Assuming that the analyzed kernel uses an alternative approach based on PIP, a tool for parametric

only the cases where the minimum is a read (and not a write) are kept. Then, following Theorem 2, it remains to add the constraints that express the fact that an operation FirstOpReadBeforeWrite(\vec{m}) belongs to a given tile \( T \). The final result is described as a relation between \( \vec{m} \) and \( T \) that can be read as a set of value \( \vec{m} \), parameterized by \( T \) to get the sets Load(\( T \)) and Store(\( T \)). Similarly, Store(\( T \)) is obtained by maximization, through the computation of LastOpWrite(\( \vec{m} \)).

Back to the example: For the left tiling of Fig. 1, computing FirstOpReadBeforeWrite(\( \vec{m} \)), for the tile strip indexed by \( I \), amounts to finding \((i, j)\) such that \((J, jj, i, j)\) is lexicographically minimum, with the constraints:

\[
\begin{align*}
& i = N - j, jj = i, j + j = m, 0 \leq i, j \leq N, \\
& bl \leq i \leq b(1 + I), bj \leq jj \leq b(j + 1) - 1
\end{align*}
\]

This system can be solved with PIP if the tile size \( b \) is fixed. After simplifications, we obtain the expression given in Section II for \( b = 10 \). Finally, given the schedule \( \theta(i, j) = (N - j, i) \), we put back the constraint \( \frac{1}{N} = T \), where \( T \) is a parameter indexing tiles, and, from this relation between \( T \) and \( \vec{m} \), we derive the set Load(\( T \)) given in Section II.

IV. APPLICATION TO HLS FOR FPGA

We now use the theory developed in Section III to generate automatically a C specification of communicating processes that can be compiled into hardware by a HLS tool, namely Altera C2H, following the procedure proposed in [5]. It remains to show how the different communication and computation processes are scheduled and synchronized, in C using C2H, how the local memories (size and access function) are then defined with respect to this schedule, and how the load and store sets are finally scanned. We point out that all these steps (computation of loads/stores, computation of a mapping for designing local buffers, scanning of sets for kernel generation) are done w.r.t. the schedule \( \theta \). This makes the whole technique transparent, without even generating an initial loop tiling.

A. Synchronization of communication/computation processes

Following the methodology of [5], we generate 5 functions (called drivers) to be translated by C2H into separate hardware accelerators. For each tile strip, the Compute driver executes all computations of tiles in sequence, whereas, for communications, the tiles are processed by pairs, by 2 load and 2 store drivers, e.g., if \( T_{\text{min}} = 0 \), Load0 and Store0 deal with even tiles, Load1 and Store1 with odd tiles. Each driver contains a loop nest iterating over the tiles. For each tile, a piece of code (called micro-kernel) performs the required loads, computations, or stores. The drivers are run in parallel and software-pipelined as shown in Fig. 2, with synchronizations implemented as blocking reads and writes in FIFOs of size 1. In C2H, nested loops are scheduled with a hierarchical finite-state machine (FSM) structure. Data fetches in loops are pipelined to hide latency. Furthermore, a special state is
added, after a precomputed constant number of cycles, that stalls the FSM until the data is received. We exploit this mechanism to guarantee the data-flow dependencies induced by the remote data transfers (blue arrows in Fig. 2) by placing the corresponding synchronizations outside the micro-kernels. On the contrary, the synchronizations used to sequentialize the accesses to the DDR (dotted arrows) are placed inside the micro-kernels, at the last iteration, i.e., as soon as the last DDR request within a tile is initiated. This avoids the important penalty due to the loop pipeline that must be drained. This way, computations and communications are pipelined and latencies are hidden. The subtleties of this implementation and the interaction with C2H specificities were detailed in [5].

For the design of local memories, we need to specify the software-pipelined schedule of the processes to know when buffer locations can be reused. Several software pipelines are possible, the one implemented in our tool is as depicted in Fig. 2. It is captured as follows. If \( T \) is the innermost tile counter (i.e., iterating on the tile strip), we add the constraint \( T = 2p \) (resp. \( T = 2p + 1 \)) to the tile domains, where \( p \) is a fresh integer variable. Then, as far as memory reuse is concerned, it is enough to specify the pipelined schedule with the following 2D schedule \( \theta_{db} \) (this is when \( T_{\min} \) is even):

\[
\begin{align*}
\theta_{db}(Load0, 2p) &= (p, 0) & \quad \theta_{db}(Load1, 2p + 1) &= (p, 1) \\
\theta_{db}(Comp, 2p) &= (p, 1) & \quad \theta_{db}(Comp, 2p + 1) &= (p, 2) \\
\theta_{db}(Store0, 2p) &= (p, 2) & \quad \theta_{db}(Store1, 2p + 1) &= (p, 3)
\end{align*}
\]

### B. Local memory management

With our method, all computations are done with variables from the local memory. The lifetime of such a variable starts at its first access (possibly resulting from a load operation) and ends at its last access (possibly resulting from a store operation). We now explain how variables are mapped in the local memory. It must be done so that (i) two data live at the same time are not mapped to the same local address, (ii) the local memory size is as small as possible.

Unlike the methods developed in [18], which try to pack data optimally (in size), possibly with complex and expensive mapping functions and reorganization, we rely on hardware-inexpensive array contraction based on modular mappings [19], [20]: an array cell \( a(\vec{i}) \) is mapped to a local array cell \( a_{lin}(\sigma(\vec{i})) \) where \( \sigma(\vec{i}) = \vec{A} \vec{i} \mod \vec{b}, \vec{A} \) is an integer matrix, and \( \vec{b} \) is an integral vector defining a modulo operation component-wise. When the array index functions are translations w.r.t. the loop indices, as in \( a[i,j-1] \), the set of live array cells is a window sliding during a tiled program execution, allowing efficient memory optimizations. The framework presented in [20] generalizes this particular situation, given an analysis of live array cells.

For code generation, a direct approach is to feed ClooG (http://www.cloog.org) with the different data sets, together with a sequential schedule. In our context however, although correct, this produces inefficient code, mostly due to C2H constraints. It is better to generate each kernel as a single “linearized” loop executing one instruction per iteration, using the Boulet-Feautrier algorithm [21]. This avoids the penalty due to the pipeline of inner loops that must be drained (see Sect. IV-A). Also, as recalled in Sect. III, accessing successively in different DDR rows degrades the throughput. With a single loop, we achieve spatial locality in the DDR accesses by scanning the different arrays one after the other, with no interleaving, and following rows, i.e., lexicographically with respect to the array indices. Furthermore, such a loop is nicely pipelined with C2H, with one DDR access per iteration.

### C. Experimental results

We implemented our methods using the polyhedral tools PIP and Polylib. Our prototype takes as input the C source code of a small kernel to be optimized. The input parameters, such as the loop tiling, are specified with pragmas. Then, a C source code, which implements a double-buffered version of the kernel, is automatically generated. It can be simulated using Linux processes, FIFOs, and shared memories (with IPC Linux library). The 5 driver codes are then synthesized using C2H, which integrates them automatically in the system instantiated using Altera SOPC builder. This C source code is generic and cannot be immediately compiled C2H. At this point, a few modifications by hand are needed, such as inserting the adequate pragmas for C2H, transforming array accesses to linearized addresses with the right base addresses, instantiating memories in the SOPC builder, changing some arrays into non-aliasing pointers so that C2H, whose dependence analyzer and software pipeliner are weak, can generate codes with the right initialization intervals, etc. These changes are minor and systematic, but they are not integrated yet in our code generator and take time when performed by hand.

The study provided in [5], for the HLS tool C2H, showed that, even for elementary kernels, generating adequate C codes that can be automatically synthesized with no additional handmade VHDL glue, while exploiting the maximal DDR bandwidth, is very tricky. But it is feasible if codes and synchronizations are written in a specific, though generic, way. Our techniques show that this process can be automated. We considered the 3 kernels studied in [5] (with the same tiling), DMA transfer, sum of vectors (VS), matrix multiply (MM), to check if we could achieve the same performance automatically. Matrix multiply, the main example demonstrated for the RStream compiler [13], is already, for circuit generation, very involved: the original code has a few lines but the hand-optimized version (a double-buffered matrix multiply by block) has more than 500 lines!

We used ModelSim to evaluate our designs, which were synthesized on the Altera Stratix II EP2S180F1508C3 FPGA, running at 100 MHz, and connected to an outside DDR memory, of specification JEDEC DDR-400 128 Mb x8, CAS of 3.0, running at 200 MHz. The optimized versions can run 6x or more faster than the direct implementations (remember that the maximal speed-up is at most 8, if we start from a code where successive DDR accesses are in different rows). Note that these speed-ups are obtained not because computations are parallelized (tiles are run in sequential), not only because the communications are pipelined (this is also the case in the original versions), but (i) because DDR requests are reorganized to get successive accesses on the same row as much as possible, (ii) because some communications overlap computations, and (iii) because some data reuse is exploited.

However, to achieve this, there is a (moderate) price to pay in terms of hardware resources, in addition to the local
memories involved to store the data locally. This is illustrated in Table I, which gives different parameters measuring the hardware usage: the number of look-up tables (column “ALUT”), of registers (“Reg.”), of registers used by the whole system (“Total reg.”), and of hard 9-bit DSP cores (“DSP”).

Compared to the manually-optimized versions, the automatic ones use slightly more ALUT and registers, mostly because they use 2 separate FIFOs for synchronization between the drivers Load0 and Load1, and the driver Compute (we changed the design of [5] to make it more generic). They also use more multipliers to perform tile address calculations, which could be removed by strength reduction.

Speed-ups are given in the column “S-U”. Optimized versions have a slightly smaller maximal running frequency than the original ones (column “Max. freq.” in MHz). But, if the designs already saturate the memory bandwidth at 100 MHz, running the systems at a higher frequency will not speed them up anyway. This maximal frequency reduction could come from more complex codes, the Avalon interconnect routing, and the use of double-port memories available in the FPGA, which induces additional synthesis constraints.

V. CONCLUSION

In the context of HLS for FPGA, we proposed an automatic translation method to optimize, at source level, a kernel linked to an external DDR memory. Our method relies on a code restructuring that combines loop tiling (specified by the user), advanced communication coalescing and data reuse, pipelining of communicating processes in a double-buffer fashion, buffer size optimization, and optimized loop linearization. It has been implemented as a prototype, and the first experimental results show that the method performs as good as our previous fully-optimized handwritten designs. To our knowledge, this is the first time, in the context of HLS, that such accelerators are automatically generated. Our method is also a generic form of kernel offloading to a distant platform and thus could be interesting in other contexts.
